

What a linear probe can read from each frozen encoder

Ridge probes on frozen mean-pooled embeddings; five folds that keep identical sequences (stability) or transcripts of one gene (GTEx) together. On stability, repeated sequences carry labels differing by a median SD of 0.49, which caps any sequence-only model near $R^2 = 0.59$, so 0.14 is about a quarter of what is reachable. Note the two panels use different x ranges.
